## **THE INSTITUTES FOR ENVIRONMENTAL RESEARCH**

The mission of the Institutes is to study the oceans, and inland waters, the lower and upper atmosphere, the space environment, and the earth, seeking the understanding needed to provide more useful services. These research Institutes are:

- The Institute for Earth Sciences
  - conducts exploratory and applied research in geomagnetism, seismology, geodesy, and related earth sciences.
- The Institute for Oceanography
  - works to increase knowledge and improve understanding of the ocean and its interaction with the total physical environment of the globe.
- The Institute for Atmospheric Sciences
  - seeks the understanding of atmospheric processes and phenomena that is required to improve weather forecasts and related services and to modify and control the weather.
- The Institute for Telecommunication Sciences and Aeronomy
  - supports the Nation's telecommunications by conducting research and providing services related to radio, infrared, and optical waves as they travel from a transmitter to a receiver. The Institute is also active in the study and prediction of periods of solar activity and ionospheric disturbance.

TABULATIONS OF VHF PROPAGATION DATA OBTAINED  
OVER IRREGULAR TERRAIN AT 20, 50, AND 100 MHz

by

M. E. Johnson, M. J. Miles, P. L. McQuate, and A. P. Barsis

This report contains tabulations of transmission loss data resulting from propagation experiments at 20, 50, and 100 MHz conducted over irregular terrain in the Colorado high plains east of the Continental Divide.

Part I: COLORADO PLAINS DATA

1. Introduction

The purpose of this report is to present tabulations of transmission loss data resulting from a propagation experiment over arbitrary terrain in the 20- to 100-MHz range. Although analysis results have already been described in several unpublished reports and in papers by Miles and Barsis (1966) and Barsis and Miles (1967), it seems appropriate to present a complete compilation of all data obtained in this program together with other pertinent information. In this way, additional analyses for specific purposes will be facilitated.

Due to the large amount of data which were collected during the measurement program, this report is in three parts. Each part contains data for one of three terrain types over which the measurements were performed, as follows:

Part I: Colorado Plains

Part II: Colorado Mountains

Part III: N. E. Ohio Hills

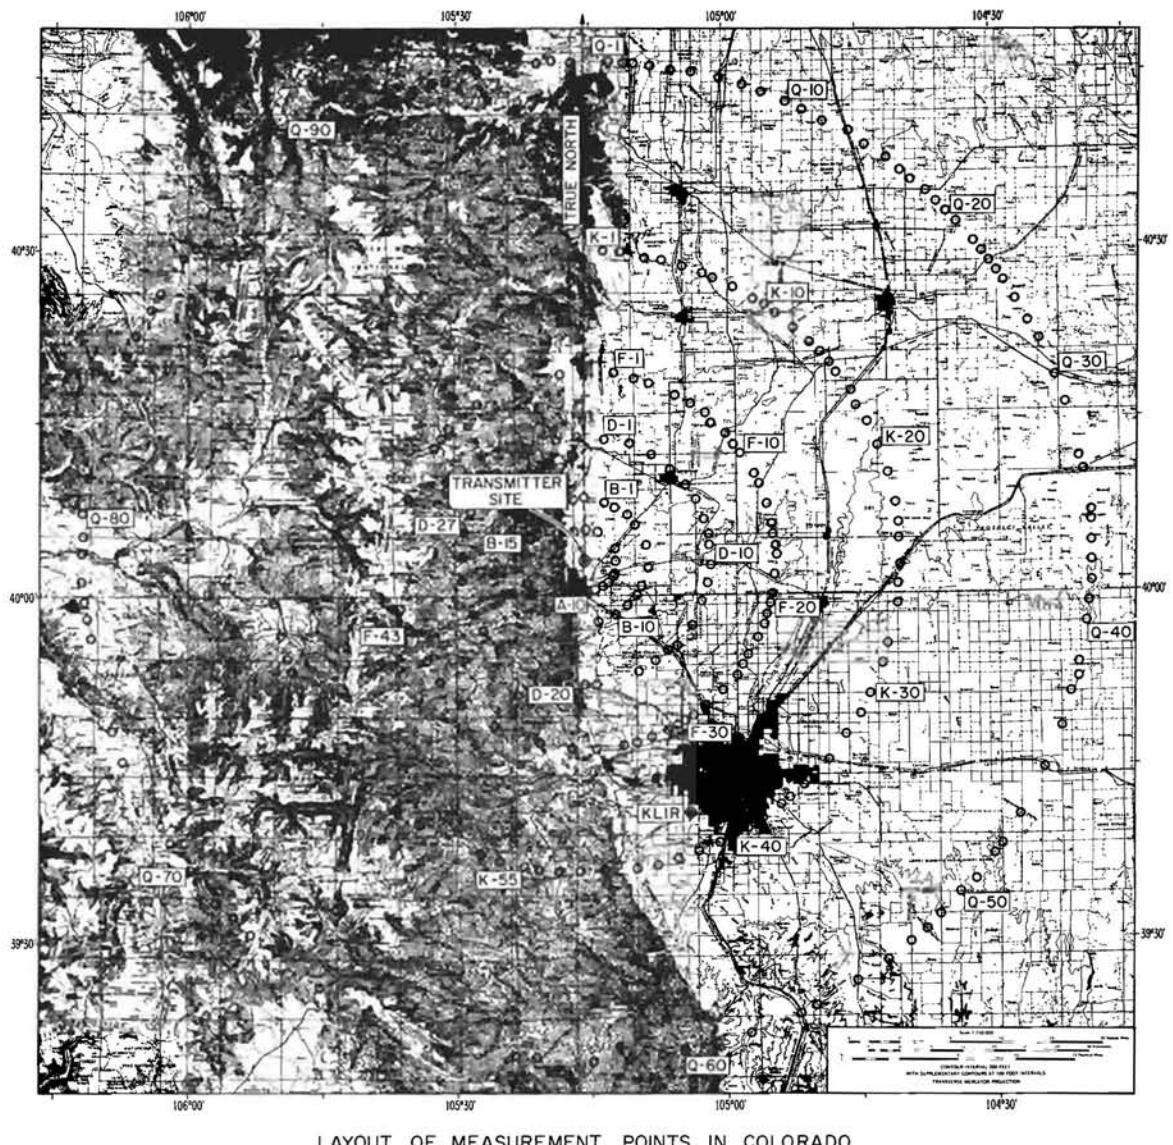

The data in each part are in the form of tables of received carrier level, basic transmission loss, and attenuation relative to free space for various path distances, frequencies, antenna heights, and combinations of transmitting and receiving antenna polarizations. For each propagation path, terrain profiles, photographs, and meteorological information are also shown. The reports also present information on antenna gain and patterns, line losses, and receiver calibration.

The measurement program which resulted in the data described here was undertaken through the sponsorship of the U. S. Army Electronics Command as part of a study of propagation characteristics under conditions resembling the operation of an army in the field. It was intended to simulate net-type vehicular operations at frequencies up to 100 MHz, with antenna heights restricted to less than 10 m above ground. The measurements were performed in Colorado by personnel of the Institute of Telecommunication Sciences and Aeronomy of the Environmental Science Services Administration (formerly the Central Radio Propagation Laboratory of the National Bureau of Standards), and in northeastern Ohio by Smith Electronics, Inc., under contract to NBS (CST-7422, dated April 10, 1963).

## 2. Measurement Program and Equipment

The tabulated data were largely obtained in 1963 and 1964; some additional data were obtained up to June 1965. For the measurements in Colorado, a transmitter site northeast of Boulder was used. Figure 1 is a map of the area showing all the measurement locations which were arranged in concentric circles around the transmitter site. Since the transmitter site is close to the plains-mountains boundary line, a portion of the receiving locations was located in the mountains, and the remainder in the relatively open eastern plains. Only vertically polarized transmissions were used for 20.084 and 49.72 MHz, whereas both vertically and horizontally polarized transmissions were used for 101.5 MHz. All transmissions from the test site northeast of Boulder were continuous wave. Additional measurements were also obtained by using the horizontally polarized signals from a commercial frequency-modulation station (KLIR-FM) located in southwest Denver, and operating on 100.3 MHz. In this way results obtained with low, and with relatively high transmitting antennas can be compared.

The data obtained in northeastern Ohio are based on the use of six different transmitter sites; this phase of the experiment will be described in Part III of this report. Frequencies of 19.97, 49.72, and 101.8 MHz were used there.

LAYOUT OF MEASUREMENT POINTS IN COLORADO

Figure 1

Descriptive antenna parameters for the Colorado data are shown in table 1. Receiving sites were selected at 5, 10, 20, 30, 50, and 80 km from the test transmitter location; several additional sites were at distances less than 5 km. The distance from KLIR-FM to the receiving sites varies from 6 to 123 km.

TABLE 1  
Descriptive Antenna Parameters

Frequency, MHz	Colorado Test Transmissions	Receiving Antennas
	Transmitting Antennas	
20.084	quarter-wave vertical, 3.3 m above ground	2-m spring-mounted vertical whip, 1.3 m above ground
49.72	quarter-wave vertical, 4 m above ground	quarter-wave spring- mounted vertical whips, 0.55 and 1.7 m above ground
101.5	quarter-wave vertical monopole horizontal loop, or 5-element Yagi, 3.15 m above ground	quarter-wave vertical monopole, and hori- zontal loop, 3, 6, or 9 m above ground

Note that for the vertically polarized antennas the height of the antenna above ground is to the feed point or to the equivalent ground plane.

KLIR-FM uses a horizontally polarized circular transmitting antenna on 100.3 MHz with the center of radiation 68.6 m above ground. Both the test transmissions and the KLIR-FM transmissions were received by the same horizontal loop antenna 3, 6, or 9 m above ground.

Further discussion of the methods used to determine antenna pattern and gain values is contained in section 4. Pictures of the measurement vehicles and the antennas appear in figures 2, 3, and 4. The transmitting Yagi antenna used for most of the 100-MHz measurements can be adjusted to positions for either horizontally or vertically polarized radiation.

The Colorado transmitting site and a close-up of the transmitting Yagi antenna (on 101.5 MHz) are shown in figures 2 and 3. The antenna (in position for horizontal polarization) is mounted on a box housing the motor which rotates the antenna to the desired position; the box itself rotates on top of the supporting pole in order to provide orientation of the antenna in any desired direction.

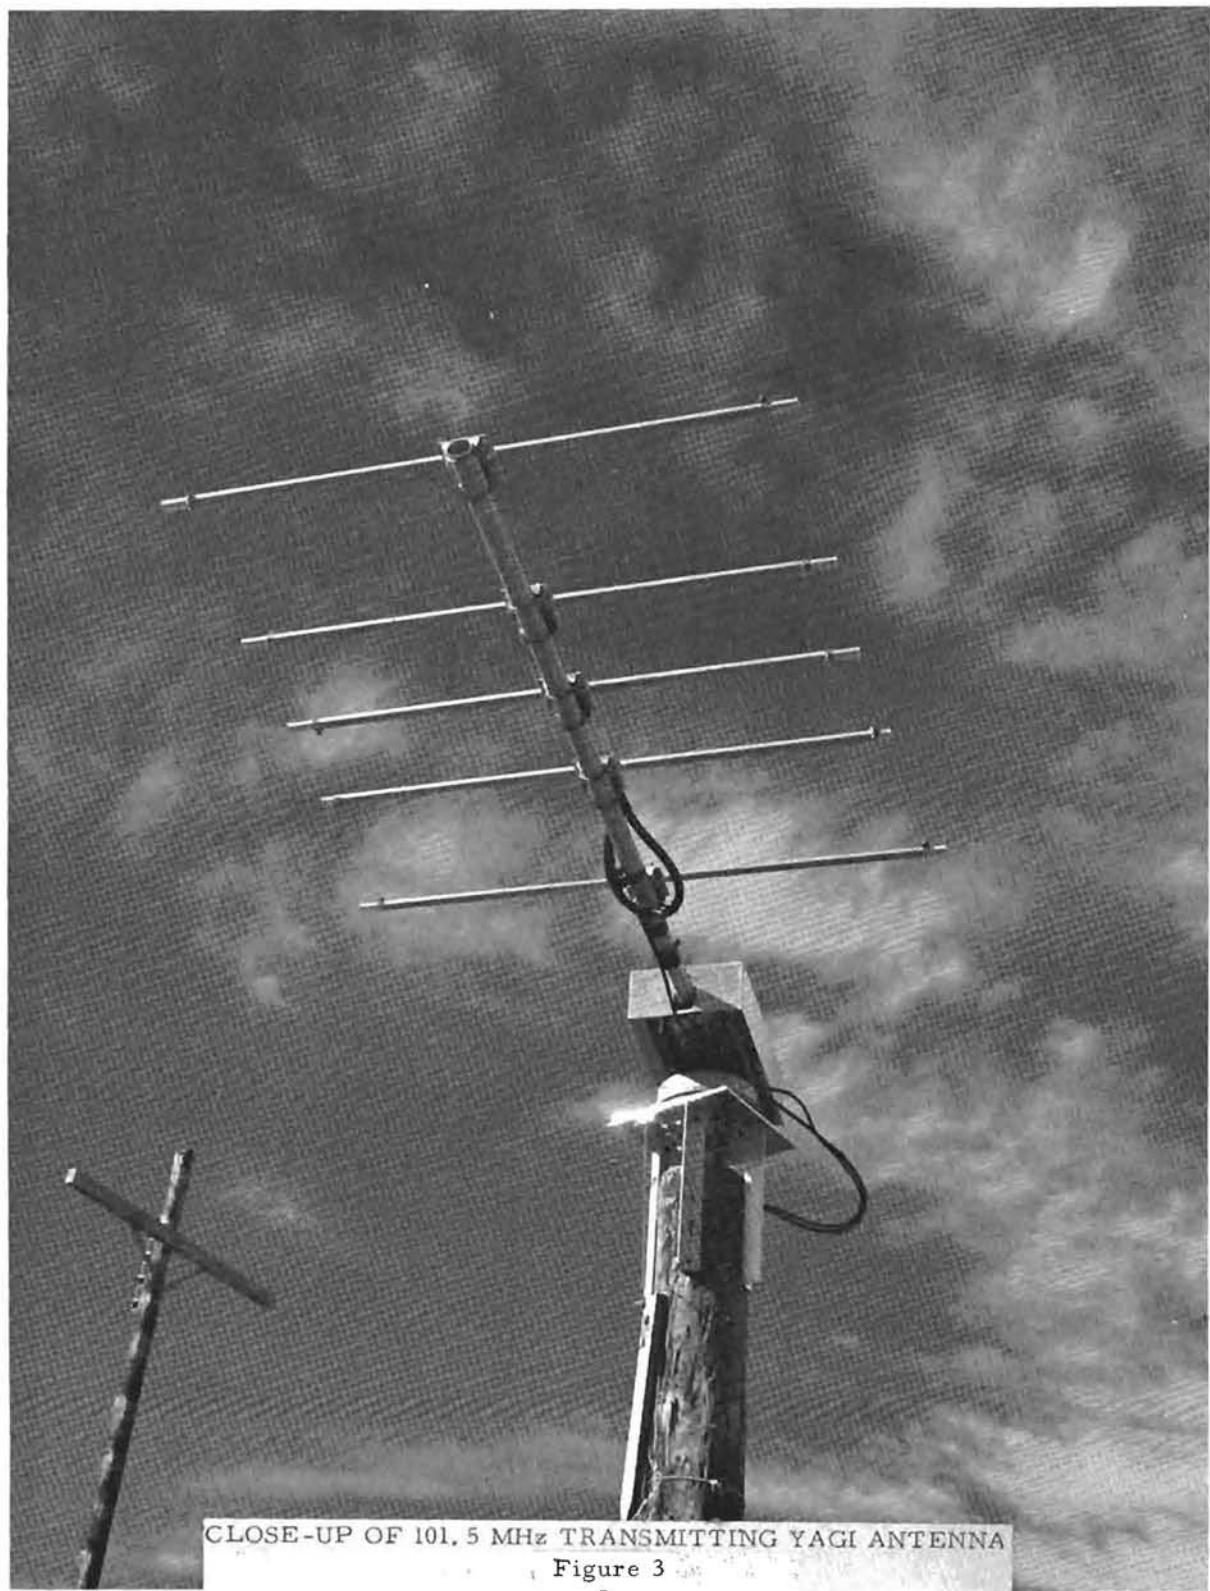

Figure 4 shows the 101.5-MHz receiving vehicle in two typical Colorado locations (open plains and on a mountain road in a canyon). The horizontal receiving antenna appears in both pictures.

### 3. Measurement Procedures

Measurement procedures were designed to simulate completely random choices of sites as well as to simulate siting improvement within limitations similar to those encountered in army field operations. Nominal, or "principal", measurement locations were first selected from a map study without considering terrain details by determining points on

Figure 2

CLOSE-UP OF 101.5 MHz TRANSMITTING YAGI ANTENNA

Figure 3

TYPICAL COLORADO MEASUREMENT LOCATIONS

Figure 4

accessible roads at distances of 5, 10, 20, 30, 50, and 80 km from the test transmitter site. An additional group of points at varying distances less than 5 km from the test transmitter site were also used. In general, adjacent measurement points were separated by at least 1 km from each other. Code designations for the measurement points are indicated in figure 1.

Since short-time variations in the received power levels were less than 1 dB at distances up to and including 50 km, the actual length of the measurement interval for each data point was considered unimportant and seldom exceeded a few seconds. At the 80-km distance, short time variations were generally more pronounced (up to 5 dB); consequently the data points were obtained by averaging received signal power levels over a period of several minutes.

The "improved siting" simulation was accomplished by a search operation for the highest received power level along accessible roads within 100 m of each principal measurement location using the 3-m antenna height first with horizontal and then with vertical polarization. However, this search procedure was not used for locations at the 80-km distance because of the short-time variations in the received power.

The detailed measurement procedure used in Colorado follows:

Measurements were first made using the vehicle equipped for operation at 100 MHz.\* The operator had in his possession detailed topographic maps on which all principal locations were clearly marked. On arriving at each location, the operator first made all required field strength measurements on 100 MHz using both horizontal and vertical polarization at the 3-, 6-, and 9-m antenna heights for the test transmissions but using only horizontal polarization for KLIR-FM. Switching from horizontally polarized to vertically polarized transmissions was accomplished on request via a two-way communication link. The transmitting antenna heights remained fixed for all measurements.

After measurements at a principal location were completed, the receiving vehicle was driven slowly over available roads within a 100-m radius of the principal location using the horizontally polarized 100-MHz test transmissions with the 3-m receiving antenna height. Thereby a point could usually be found where the receiving power level was a maximum. At this point, which is designated "alternate horizontal location" (AH in the attached tabulations), a complete additional series of measurements was made as before, but such measurements were omitted if the horizontal search procedure did not yield an alternate location where the received power level was noticeably higher (at least 1 dB) than that at the principal location.

---

\* In this and subsequent discussions, nominal frequency values will be used for brevity.

The same search procedure was then used with vertically polarized signals at 100 MHz with the 3-m antenna height. Thus an "alternate vertical location" (AV) was located and the complete series of measurements was again performed there, unless no location could be found during the search procedure where the received power level was noticeably higher (at least 1 dB) than at the principal location.

When the received 100- MHz power levels for the 3-m antenna height at one or both of the alternate locations (AH or AV) were not materially different from the values obtained at the principal location, no additional set of measurements was made at that alternate site, and the results obtained from the principal location were used to characterize one or both alternate locations.

It already has been noted that the search procedure described above was not used for sites on the 80-km circle, because of the time variations which became noticeable at this distance. Consequently, data for alternate locations were not obtained at the 80-km distance.

At a later date the measurement vehicle equipped for 20- and 50-MHz operation was driven to exactly the same principal and alternate locations used at 100 MHz, and the required measurements were then performed. Only vertical polarization was used with the 3-m nominal antenna height at 20 MHz and with 1- and 3-m nominal antenna heights at 50 MHz.

The designations "alternate horizontal" and "alternate vertical" refer only to the polarization used during the search procedure for locations so designated. Once the alternate horizontal and the alternate vertical locations were established, the measurement series performed at each of the two alternate locations included both polarizations on 100 MHz and all antenna heights. In this way, transmission loss values can be compared not only for the condition of polarization and antenna height under which the search was made, but also additional data are available for a study of the effect of the bias introduced by the search procedure on other possible operating conditions. The data, as an example, will show whether an optimum location within a given small area for horizontal operation with 3-m receiving antenna height at 100 MHz is also likely to be an optimum location for different antenna heights, or for vertical polarization, or for a different frequency.

The decibel difference in the basic transmission loss values recorded for the same frequency, polarization, and receiving antenna height at the principal and at one of the alternate locations is defined as "location gain". In terms of receiving signal power level it must always be a positive quantity for 100 MHz at the 3-m receiving antenna height by definition of the search procedure. However, when antenna patterns are taken into account in the conversion of the raw data to basic transmission loss, negative values of location gain may occasionally be

obtained due to changes in antenna orientation between the principal and the alternate locations (Barsis and Miles, 1967).

#### 4. Pattern and Gain Measurements on Transmitting and Receiving Antennas

Measurements of antenna gains and patterns at the frequencies used in this program proved difficult, especially at 20 and 50 MHz. Here the antennas cannot be considered to be in free space; the influence of the vehicles and of other mounts, of the ground, and of the surroundings are of extreme importance but cannot be readily evaluated. Since the wide range of observed field strength values is a result of the terrain along the path and around the terminals, it cannot be determined accurately how much of these field strength variations can be directly ascribed to effects of the antenna environment on the characteristics of the antenna itself.

One reasonable approach of obtaining antenna performance characteristics is to measure gain and pattern data in a controlled environment such as a test range. Using these data in the conversion from measured received power levels to basic transmission loss, all variations in the antenna characteristics are lumped into the effects of the entire path. Another alternative would be to make detailed antenna measurements at every measuring point; this is obviously impractical, and probably not even theoretically justified.

Test range measurements by comparison with standard dipoles could be accomplished relatively simply with the 100-MHz antennas. In these measurements, the complete vehicular installation was used, so that the results reflect the influence of the vehicle, and may be considered to be quite reliable except possibly for cross-polarization.

Antenna gain values obtained in this way were plotted in terms of gains in decibels relative to an isotropic radiator versus azimuth. The azimuth was measured from the front of the measuring vehicle in a clockwise direction. Since the orientation of the vehicle is known for each measurement point, the correct gain value may be readily determined. The 100-MHz Yagi transmitting antennas were always oriented with their maximum toward the receiving point so that their gain is a constant for all measurements, and their horizontal antenna patterns need not be considered in this study.

For the 20- and 50-MHz antennas, pattern measurements of the receiving antennas were performed similarly several times at two different locations, using a remote target transmitting antenna. The rms deviations of three patterns obtained for the same antenna were all less than 1 dB.

Gain measurements at 20 and 50 MHz were partially obtained by comparison with values derived from calibrated field strength meters, and by the "proof-of-performance" method. The latter method,

commonly used for measuring the effective field of standard broadcast transmitting antennas (550 to 1600 kHz), consists in measuring field strength along one or more radials at various distances from the transmitting antenna, and matching the values obtained against standard curves previously calculated as a function of frequency and ground constants. In this way, the unattenuated field and the effective radiated power can be estimated.

This method is well suited to frequencies in the standard broadcast band, where the space wave can be neglected, antennas are on the ground, and propagation is entirely by the surface wave mechanism. However, the 20- and 50-MHz measurement program is different not only in frequency, but also in the height and arrangement of the antennas. The antennas are not on the ground and do not have an extensive ground system simulating a perfectly conducting plane surface. Furthermore, at 50 MHz several distinct receiving antenna heights had to be considered, and one of the field strength meters used in the tests was not designed to be operated close to the ground at an elevation comparable to that of the lower bumper-mounted receiving antenna.

One must conclude therefore that the 20- and 50-MHz antenna gain measurements can only be considered accurate within plus or minus 3 dB; thus, all basic transmission loss values at 20 and 50 MHz given in the main body of this report may be in error by this amount.

HORIZONTAL PATTERNS FOR COLORADO

RECEIVING ANTENNAS  
RELATIVE VOLTAGE (RMS VALUE = 1)

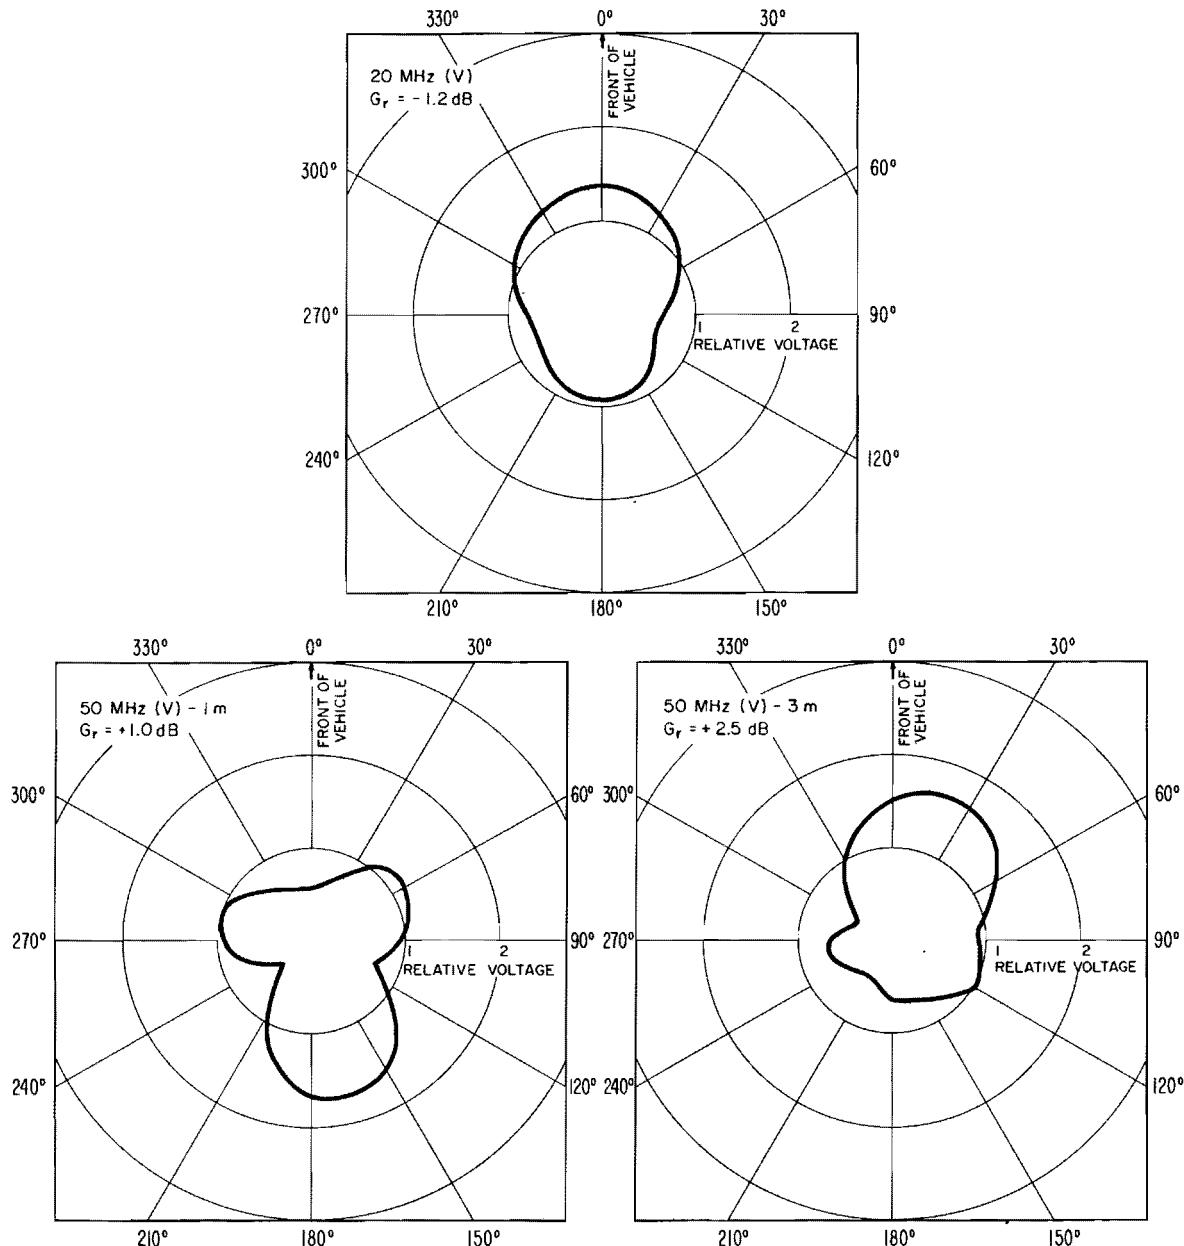

Figure 6

HORIZONTAL PATTERNS FOR COLORADO 100 MHz  
RECEIVING ANTENNAS  
RELATIVE VOLTAGE (RMS VALUE = 1)

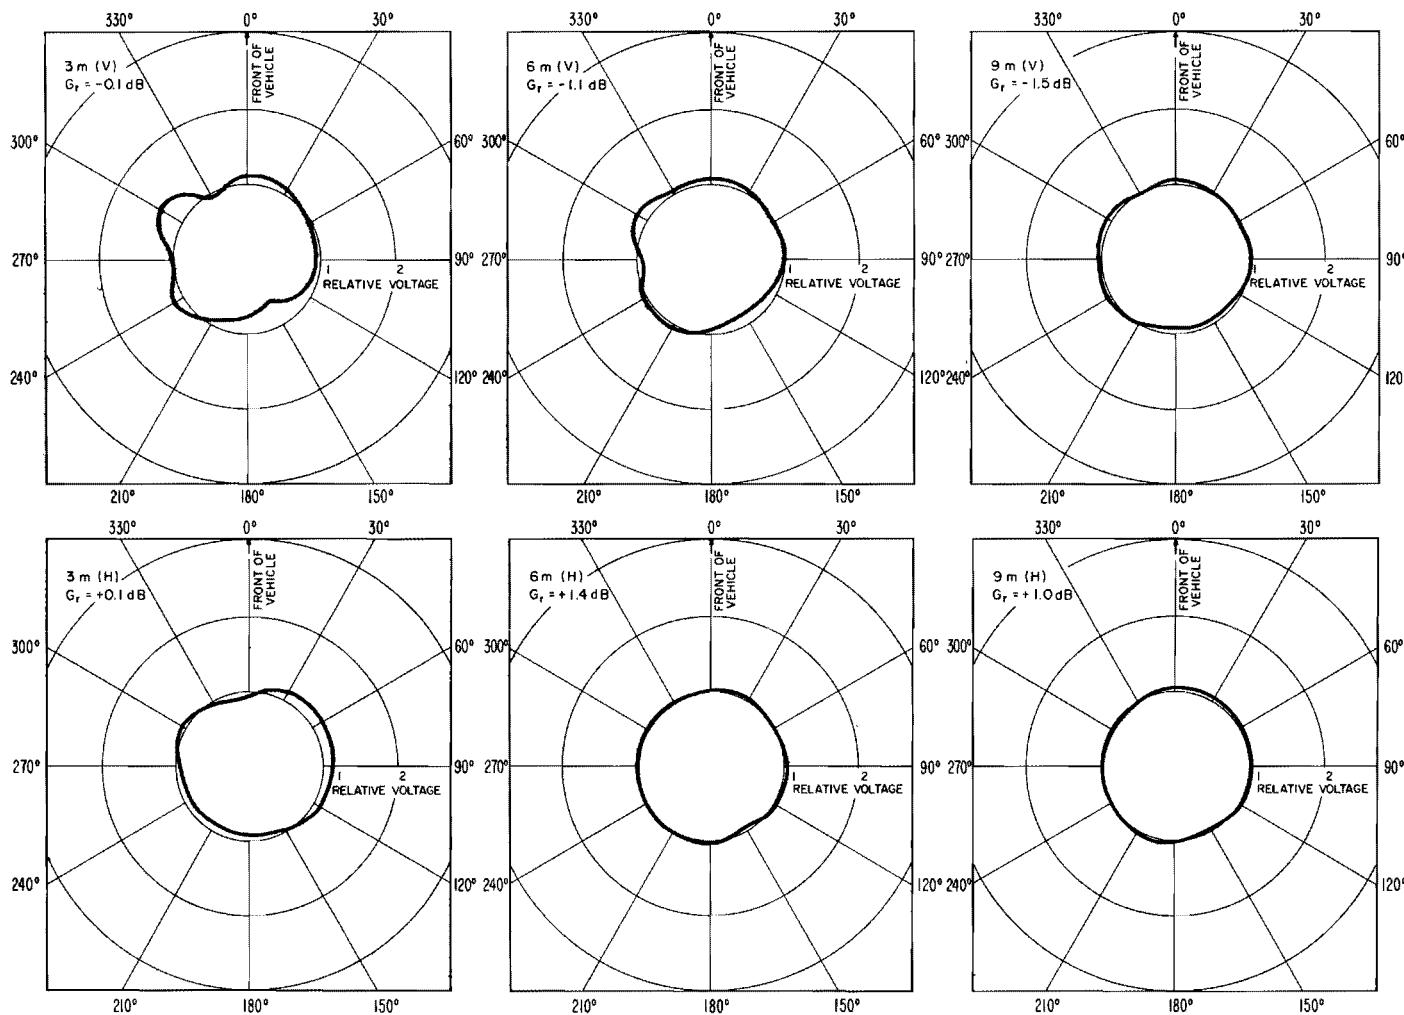

Figure 7

This is especially reflected in the apparent height gain relations at 50 MHz between the low (nominally 1 m) and the high (nominally 2 or 3 m) receiving antennas.

Table 2 shows the best estimates of rms antenna gain values for all antennas used in the measurement program. The horizontal patterns for the antennas used are shown in figures 5 through 7 in terms of voltage relative to unity rms values.

TABLE 2

Tabulation of Root-Mean-Square Antenna Gain Values  
in Decibels Relative to Isotropic Radiator

<u>Transmitting Antennas</u>	<u>RMS Antenna Gain, dB</u>
20 MHz V	- 2.6
50 MHz V	- 1.3
100 MHz (low gain) V*	- 0.4
100 MHz (low gain) H*	+ 1.3
100 MHz (Yagi) V	+ 7.6
100 MHz (Yagi) H	+ 9.6

\* Used only for 44 measurement points at 20 and 30 km in Colorado.

Table 2 (Continued)

<u>Receiving Antennas</u>	<u>RMS Antenna Gain, dB</u>
20 MHz V	- 1.2
Low 50 MHz V (1 m)	+ 1.0
High 50 MHz V (3 m)	+ 2.5
100 MHz - 3 m V	- 0.1
100 MHz - 6 m V	- 1.1
100 MHz - 9 m V	- 1.5
100 MHz - 3 m H	+ 0.1
100 MHz - 6 m H	+ 1.4
100 MHz - 9 m H	+ 1.0

Note that the rms values shown in table 2 were not used in the actual conversions of received power levels to basic transmission loss; the conversions were based entirely on gain values read off the plotted antenna patterns. The rms values, however, give some indication of the efficiency of the antennas used. The influence of the measurement vehicles is especially apparent in the comparison of the values for 100 MHz at the three antenna heights.

Pattern and gain values for the 100-MHz receiving antennas for cross-polarization are not shown. Measurements on the antenna range

yielded values between -10 and -15 dB relative to an isotropic radiator. However, the data tabulations in section 8 show somewhat unrealistic results when these values are used for conversion of the measurement results to basic transmission loss. (This will be discussed in section 5.)

## 5. Presentation of Data

Section 8 of this part of the report contains measurement data for the Colorado plains, i.e., for those sites which are located in relatively open country (usually designated "high plains"), east of the Front Range of the Rocky Mountains in Colorado.

The data are arranged by receiving sites, and two pages are used for each site. The first page for each site contains data for 20 and 50 MHz (except for the 80-km sites where only 100-MHz measurements were made), a photograph taken from the principal location in the direction toward the test transmitter site, and a path profile plotted on the basis of an effective earth radius of 8330 km, corresponding to a surface refractivity value  $N_s = 290$ . The photograph was usually taken at the time the measurements on 100 MHz were made. The second page for each site contains the 100-MHz data, a description of the principal location and surroundings, and a summary of meteorological data taken at the time the 100-MHz measurements were made. Note that different receiving vehicles were used for the measurements at 100, and at 20

and 50 MHz, and that these measurements were generally made at different times of the year.

The data presented here are in computer printout format; the path profiles were also obtained from the use of a computer program and an automatic plotter. Distances (in kilometers) to the test transmitter site are shown in the headings and are designated by "B". Each line of the printout represents a different combination of frequency, antenna height, polarization, and location (principal or alternates). The various columns are designated and explained as follows:

Column 1, location designation (in parenthesis)

T .....	terrain type, PLNS, for Colorado plains, test transmissions. Data from KLIR-FM are designated by "KLIR" instead of "PLNS", but all data shown in this part of the report are "plains" data.
B .....	distance from test transmitter site in kilometers
F .....	nominal carrier frequency in MHz
P(T) ...	polarization of transmitted signal (vertical, V, or horizontal, H)
P(R) ....	polarization of receiving antenna (vertical, V, or horizontal, H)
L .....	location (principal, P, alternate vertical, AV, or alternate horizontal, AH)

H ..... nominal receiving antenna height above ground . Note that for 50 MHz, H = 1 denotes the lower antenna mounted on the vehicle bumper, and H = 3 the higher antenna mounted on the vehicle roof. Exact values of antenna height are given in table 1 (see section 3 of this part).

Column 2, transmitter power

W(T) .... transmitter output power in dBW for test transmitter. For KLIR-FM, W(T) is the effective radiated power in dBW.

Column 3, received carrier level

W(R) .... received carrier level in dBW. The values shown here have not been corrected for signal generator calibration bias (see below).

Column 4, transmitting antenna gain

G(T) .... transmitting antenna gain in the direction to the receiving site in dB relative to an isotropic radiator. No values are shown for KLIR-FM, as the transmitting antenna gain is part of the effective radiated power value.

Column 5, receiving antenna gain

G(R) .... receiving antenna gain in dB relative to an isotropic radiator in the direction to the transmitting source (test transmitter or KLIR-FM) .

Column 6, transmitter line loss

L(T) .... line and circulator losses between transmitter and transmitting antenna input. No values are shown for KLIR-FM, as they are part of the effective radiated power .

Column 7, receiver line loss

L(R) .... line and circulator losses between the receiving antenna terminal and the receiver input

Column 8, basic transmission loss

L(B) .... basic transmission loss, in dB, obtained from the data in preceding column by the following formula:

$$L(B) = W(T) + G(T) + G(R) - L(T) - L(R) - W(R) + S(G) .$$

All terms are in decibels. S(G) is a correction for signal generator calibration bias, which was equal to zero for the 20-and 50-MHz data. For 100 MHz, S(G) = 0.6 dB for the earlier data at the 20 and 30 km distances when the low-gain transmitting antennas were used. For all other data, S(G) = 6.1 dB.

Column 9, attenuation below free space

A .... attenuation below free space in dB, obtained from basic transmission loss by subtracting the free space loss  $L_{bf}$ :

$$L_{bf} = 20 \log_{10} F + 20 \log_{10} B + 32.45 ,$$

where F is the frequency in MHz, and B the path distance in km.

In the conversion of received power levels to basic transmission loss, it was assumed that the free-space gain values of the antennas (as estimated from antenna measurements) were realized, and that antenna

circuit losses and multipath coupling losses could be neglected. These assumptions are questionable in the case of the cross-polarization data. Inspection of data tabulations shows in most cases unrealistically low values for basic transmission loss (or attenuation below free space) for the cross-polarization data as compared to co-polarization data. The differences are especially great when vertically polarized signals were received using the horizontally polarized receiving antenna. It is quite likely that the antenna gain values used for cross-polarization are not realistic, since they were determined on an antenna range under relatively ideal conditions and may not resemble the values obtained at the various receiving sites. Also, signal pick-up from transmission lines may have a substantial effect on the apparent received power level under the cross-polarized condition. If any evaluation of cross-polarization data (... H, V...), or (...V, H...) is attempted, it should be based on values of the received power level  $W(R)$ , rather than on the basic transmission loss values  $L(B)$  for each site, although such an evaluation would include the effect of the antennas, and would be less generally applicable. Further analysis of the cross-polarization data will be included in a later report.

## 6. Acknowledgements

Essentially all personnel within the Spectrum Utilization Research Program Area of the Tropospheric Telecommunication Laboratory participated in the collection, analysis, and evaluation of the data. Special recognition should be given to Mrs. M. G. Frank for her work in assembling the data tabulations and profiles. Tabulation of the profile data was accomplished with the assistance of personnel of the Tropospheric Propagation Prediction program area.

## METEOROLOGICAL DATA AND COMMENTS OF OPERATOR

DATE	BAROMETRIC PRESSURE	CLOUD TYPE	COVER PERCENT	ASSMAN WET	DRY
04-14-64	24.95	L1,H1	60%	46.5	68.0

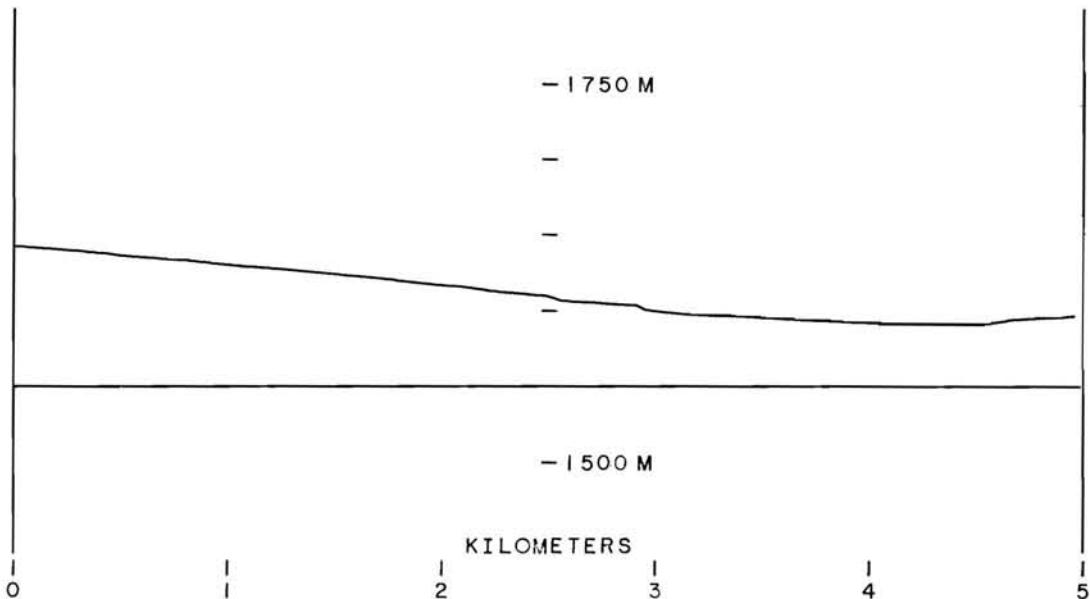

ROW OF TREES 40FT HIGH FORM LINE OF SIGHT HORIZON 1/2 MILE TO THE WEST  
 AREA IS OPEN GRASSLAND EXCEPT FOR LINE OF 60FT TREES 400FT DUE WEST.  
 4-WIRE HIGH VOLTAGE PUBLIC SERVICE TRANSMISSION LINE RUNS EAST-WEST  
 ACROSS ROAD 197FT NORTH OF NORTH END LIMIT OF SEARCH AREA.
